Peter J. Bickel is Professor of Statistics, University of California, Berkeley 97420. Joseph A. Yahav is Professor of Statistics, Hebrew University, Jerusalem, Israel. This work was partially supported by ONR contract N00014-80-C0163.

We are indebted to Persi Diaconis for referring us to Kuipers and Niederreiter (1978) enabling us to obtain a considerable simplification of our original proof of the theorem in the appendix. We also thank Adele Cutler for the programming of the simulations and other calculations of section 3.

#### Abstract

Simulation methods, in particular Efron's (1979) bootstrap, are being applied more and more widely in statistical inference. Given data, $\left(X_{1}, \cdots, X_{n}\right)$, distributed according to $\mathbf{P}$ belonging to a hypothesized model $\mathbf{P}$ the basic goal is to estimate the distribution $L_{P}$ of a function $T_{n}\left(X_{1}, \cdots, X_{n}, P\right)$. The bootstrap presupposes the existence of an estimate $\hat{P}\left(X_{1}, \cdots, X_{n}\right)$ and consists of estimating $L_{P}$ by the distribution $L_{n}^{*}$ of $\mathrm{T}_{\mathrm{n}}\left(\mathrm{X}_{1}^{*}, \cdots, \mathrm{X}_{\mathrm{n}}^{*}, \hat{\mathrm{P}}\right)$ where $\left(\mathrm{X}_{1}^{*}, \cdots, \mathrm{X}_{\mathrm{n}}^{*}\right)$ is distributed according to $\hat{\mathrm{P}}$. The method is particularly of interest when $\mathbf{L}_{\mathrm{n}}^{*}$, though known in principle, is realistically only computable by simulation.

Such computation can be expensive if n is large and $\mathrm{T}_{\mathrm{n}}$ is very complex - see for instance the multivariate goodness of fit tests of Beran and Millar (1985). Even when application of the bootstrap to a single data set is not excessively expensive, Monte Carlo studies of the bootstrap are another matter.

We propose a method based on the classical ideas of Richardson extrapolation for reducing the computational cost inherent in bootstrap simulations and Monte Carlo studies of the bootstrap by doing the simulations for statistics based on two smaller sample sizes.

We study theoretically which ratio of the two small samples sizes is apt to give us best results. We show how our method works for approximating the $\chi^{2}, t$ and smoothed binomial distributions and for setting bootstrap percentile confidence intervals for the variance of a normal distribution with mean 0 .

KEY WORDS: cost of computation, Edgeworth, approximation.

## 1. INTRODUCTION

Let $L_{n}^{*}$, as in the abstract, be the bootstrap distribution of a statistic $T_{n}\left(X_{1}, \ldots, X_{n}, P\right)$. With knowledge of particular features of $\mathbf{L}_{n}^{*}$ various devices such as importance sampling can be used to reduce the number $r$ of Monte Carlo replications needed to compute (or rather estimate) $L_{n}^{*}$ closely. The total cost of computation for a simulation is proportional to $c(n) r$ where $c(n)$, the cost of computing $T_{n}$, usually rises at least linearly with $n$ and often faster. In this note we explore a way of reducing $c(n)$ rather than $r$. To fix ideas suppose $T_{n}$ is univariate and let $F_{n}{ }^{*}$ be the distribution function of $\mathrm{L}_{n}^{*}$. For most statistics $T_{n}$ of interest, it is either known or plausible to conjecture that $F_{n}{ }^{*}$ tends to a limit $A_{0}$ in probability

$$
\begin{equation*}
F_{n}^{*}(x)=A_{0}(x)+o_{p}(1) \tag{1.1}
\end{equation*}
$$

for all $x$ and often uniformly in $x$ as well. Examples, see, for instance, Bickel and Freedman (1981), are the usual pivots for parameters $\theta(F)$ when $X_{1}, \cdots, X_{n}$ are i.i.d. $F$ and $\hat{P} \longleftrightarrow \hat{F}$ is the empirical distribution. Thus if $T_{n}=\sqrt{n}(\theta(\hat{F})-\theta(F))$ then $A_{0}=\mathbf{N}\left(0, \sigma^{2}(F)\right)$ under mild conditions, and if $T_{n}=\sqrt{n} \frac{(\theta(\hat{F})-\theta(F))}{\sigma(\hat{F})}$ then
$A_{0}=\mathbf{N}(0,1) . \quad A_{0}$ can also be known to exist but not be readily computable. For example let $T_{n}=\sqrt{n} \sup _{x}|\hat{F}(x)-F(x)|$ with $F$ possibly discrete, a situation discussed in Bickel and Freedman (1981). Even more, an asymptotic expansion in powers of $n^{-1 / 2}$ is known to be true in some cases and reasonable to conjecture in many others. That is,

$$
\begin{equation*}
F_{n}^{*}(x)=A_{0}(x)+\sum_{j=1}^{k} n^{-j / 2} A_{j}(x)+O_{P}\left[n^{\frac{-(k+1)}{2}}\right] \tag{1.2}
\end{equation*}
$$

The most important special cases arise when $A_{0}$ is normal and the expansion (1.2) is of Edgeworth type. Examples of such expansions appear in the context of the bootstrap in Singh (1981), Bickel and Freedman (1981), Abramowitz and Singh (1985) etc. Expansions for the distributions $F_{n}$ of statistics $T_{n}\left(X_{1}, \cdots, X_{n}\right)$ under fixed $F$ have been extensively studied - see for example Bhattacharya and Ranga Rao (1976).

In this context, our proposal is to calculate $F_{n_{1}}, \cdots, F_{n_{k+1}}$ where,

$$
\begin{equation*}
n_{1}+\cdots+n_{k+1}=b \ll n . \tag{1.3}
\end{equation*}
$$

We use the $F_{n_{j}}$ to approximate $F_{n}$. This procedure is classically used in numerical analysis, where it is called Richardson extrapolation, as a way of approximating $F_{\infty}$. Our application of these ideas differs in that,
i) We are interested in $F_{n}$, not $F_{\infty}$
ii) $\quad F_{\infty}$ is sometimes known, as in the Edgeworth case, and can be used to improve the approximation
iii) We are interested in the design problem of selecting the $n_{j}$ subject to the 'budget" constraint (1.3).

The use of our method in the bootstrap context just involves putting * on the $F_{n_{j}}$, $F_{n}$. We develop the method in detail in the next section and give explicit solutions to three formulations of the design problem for $k=1$. Finally in section 3, we test our method on approximations of known $F_{n}$ as well as some bootstrap examples. The results are very encouraging.

## 2. EXTRAPOLATION

Throughout this section (I-K) will refer to Isaacson and Keller (1966). Write $t=n^{-1 / 2}, 0<t \leq 1$. We are given a sequence of distribution functions $F_{n} \stackrel{\Delta}{\Delta} G_{t}$ and write,

$$
\begin{align*}
& G_{t}=P_{t}+\Delta_{t}  \tag{2.1}\\
& P_{t}=A_{0}+\sum_{j=1}^{k} t^{j} A_{j}
\end{align*}
$$

The argument in the functions $G_{t}, A_{j}$ plays no role in our discussion and is omitted. We calculate $G_{t_{0}}, \cdots, G_{t_{k}}, t<t_{0}<\cdots<t_{k}$. If $\Delta_{t}=0$ for $t, t_{0}, \cdots, t_{k}$ we obtain $G_{t}$ perfectly from the $G_{t_{j}}$ by using the Lagrange interpolating polynomial, (I-K p.188)

$$
\begin{equation*}
\hat{G}_{t}=\sum_{j=0}^{k} G_{t_{j}} \phi_{k, j}(t) \tag{2.2}
\end{equation*}
$$

$$
\phi_{k, j}(t)=\Pi_{i \neq j}\left[\left(t-t_{i}\right) /\left(t_{j}-t_{i}\right)\right] .
$$

In particular for the only case we study in detail, $k=1$,

$$
\begin{equation*}
\hat{G}_{t}=\left(t_{1}-t_{0}\right)^{-1}\left[\left(t_{1}-t\right) G_{t_{0}}+\left(t-t_{0}\right) G_{t_{1}}\right] . \tag{2.3}
\end{equation*}
$$

We consider three classes for $\Delta$ depending on a parameter $M$

$$
\mathbf{D}_{1}=\left\{\Delta: \frac{d^{k+1} \Delta_{t}}{d t^{k+1}} \text { exists and sup }\left|\frac{d^{k+1} \Delta_{t}}{d t^{k+1}}\right| \leq M\right\} .
$$

Since $\Delta$ is only defined at the points $n^{-1 / 2}, n=1,2, \ldots$ we interpret $\Delta \in D_{1}$ as applying to some smooth function agreeing with $\Delta$ at all points $n^{-1 / 2}$. Our other two classes make no smoothness assumptions on $\Delta$.
$\mathrm{D}_{2}=\left\{\Delta: \sup _{t} t^{-(k+1)}\left|\Delta_{t}\right| \leq M\right\}$
$\mathrm{D}_{3}=\left\{\Delta: 0 \leq t^{-(k+1)} \Delta_{t} \leq M\right.$ for all $t>0$ or $-M \leq t^{-(k+1)} \Delta_{t} \leq 0$ for all $\left.t>0\right\}$.
For fixed $t, t_{0}, \cdots, t_{k}$ we define the error of approximation by,

$$
E_{i}\left(t, t_{0}, \cdots, t_{k}\right)=\sup \left\{\left|\hat{G}_{t}-G_{t}\right|: \Delta \in \mathbf{D}_{i}\right\}, 1 \leq i \leq 3 .
$$

We want to minimize $E_{i}$ subject to a fixed budget $b$

$$
\begin{equation*}
\sum_{j=0}^{k} t_{j}^{-2}=b \tag{2.4}
\end{equation*}
$$

If $t_{j}$ satisfy (2.4) and $b \rightarrow \infty$ then $t_{0} \rightarrow 0$.

We claim that,

$$
\begin{align*}
& E_{1} \sim \frac{M}{(k+1)!} \prod_{j=0}^{k}\left(t_{j}-t\right)  \tag{2.5}\\
& E_{2} \sim M\left\{\sum_{j=0}^{k}\left|\phi_{k, j}(t)\right| t_{j}^{k+1}+t^{k+1}\right\}  \tag{2.6}\\
& E_{3} \sim M\left\{\left[\sum_{j=0}^{k}\left[\phi_{k, j}(t)\right]_{+} t_{j}^{k+1}\right] \vee\left[\sum_{j=0}^{k}\left[\phi_{k, j}(t)\right]_{-} t_{j}^{k+1}\right]+t^{k+1}\right\} \tag{2.7}
\end{align*}
$$

where $a_{+}=a \vee 0, a_{-}=-\left(a_{\Lambda} 0\right)$. To check (2.5) apply theorem $1 \mathrm{p} .190(\mathrm{I}-\mathrm{K})$ according to which,

$$
\begin{equation*}
G_{t}-\hat{G}_{t}=[(k+1)!]^{-1} \prod_{i=0}^{k}\left(t-t_{i}\right) \frac{d^{k+1} G_{t}}{d t^{k+1}}(\xi) \tag{2.8}
\end{equation*}
$$

where $t<\xi<t_{k}$. Note that $\frac{d^{k+1}}{d t^{k+1}} P_{t}=0$. To check (2.6), (2.7) note that, interpolation is linear so that

$$
\hat{G}_{t}=\hat{P}_{t}+\hat{\Delta}_{t} .
$$

Since $P_{t}=\hat{P}_{t}$, we have

$$
G_{t}-\hat{G}_{t}=\Delta_{t}-\hat{\Delta}_{t}
$$

and (2.6), (2.7) follow from (2.2). From (2.5), $E_{1}$ is minimized subject to (2.3) as $b \rightarrow 0$ by

$$
\begin{equation*}
t_{0}=\cdots=t_{k}=\sqrt{\frac{(k+1)}{b}} \tag{2.9}
\end{equation*}
$$

The allocation (2.9) is, of course, not feasible since the $t_{j}$ must be distinct. However the clear moral is that if the error term $\Delta$ is sufficiently smooth the $n_{j}$ should be chosen as nearly equal to each other as possible.

This is analogous to the prescription appearing in the leave one out jackknife. The argument for doing so in that situation rather than leaving more out has more to do with the polynomially increasing number of subsets that need be considered. This conclusion is clearly valid not just under (2.4) but under any reasonable symmetric side condition on $t_{0}, \cdots, t_{k}$. If we suppose $t=o\left(t_{0}\right)$, i.e. the budget is much smaller
than $n$ we can simplify (2.6) to,

$$
\begin{equation*}
E_{2} \sim M\left(\Pi_{j=0}^{k} t_{j}\right) \sum_{j=0}^{k} t_{j}^{k}\left[\Pi_{i<j}\left(t_{j}-t_{i}\right) \Pi_{i>j}\left(t_{i}-t_{j}\right)\right]^{-1} \tag{2.10}
\end{equation*}
$$

and (2.7) to

$$
\begin{equation*}
E_{3} \sim M\left(\Pi_{j=0}^{k} t_{j}\right) \sum_{j=0}^{k} t_{j}^{k}\left\{\left[\Pi_{i \neq j}\left(t_{j}-t_{i}\right)\right]_{+} \wedge\left[\Pi_{i \neq j}\left(t_{j}-t_{i}\right)\right]_{-}\right\}^{-} \tag{2.11}
\end{equation*}
$$

Evidently (2.10) is minimized asymptotically by

$$
t_{j}^{-2}=\lambda_{j}^{2} b
$$

where $\lambda_{j}>0$,

$$
\begin{equation*}
\sum_{j=0}^{k} \lambda_{j}^{2}=1 \tag{2.12}
\end{equation*}
$$

and $\lambda_{0}, \cdots, \lambda_{k}$ minimize,

$$
\begin{equation*}
\left(\Pi_{j=0}^{k} \lambda_{j}\right)^{-1} \sum_{j=0}^{k}\left[\lambda_{j} \Pi_{i<j}\left(\lambda_{i}-\lambda_{j}\right) \Pi_{i>j}\left(\lambda_{j}-\lambda_{i}\right)\right]^{-1} \tag{2.13}
\end{equation*}
$$

subject to (2.12). This minimization can be carried out, in principle, for any $k$. The explicit solutions for the cases we are primarily concerned with, $E_{2}$ and $E_{3}$ for $k=1$ are as follows, if we ignore the restriction that the $\lambda_{j}^{2} b$ are integers. For $E_{2}$

$$
\begin{equation*}
\lambda_{0}^{2}=1-\lambda_{1}^{2}=.89 \tag{2.14}
\end{equation*}
$$

or more specifically

$$
\lambda_{0}=\cos \left[\frac{1}{2}\left(\sin ^{-1} \frac{1}{\omega_{0}}\right)\right]
$$

where $\omega_{0}=\frac{1+\sqrt{5}}{2}=1.6180$ is the unique positive root of,

$$
\omega^{3}-2 \omega-1=0
$$

To see this note that for $k=1$, (2.13) is just $\left(\lambda_{0} \lambda_{1}\right)^{-1}\left(\lambda_{0}-\lambda_{1}\right)^{-1}\left(\lambda_{0}+\lambda_{1}\right)$. Substitute $\lambda_{0}=\cos \theta$ to get as objective,

$$
2(1+\sin 2 \theta)(\cos 2 \theta \sin 2 \theta)^{-1}
$$

and then substitute $\sin 2 \theta=\sqrt{1-v^{2}}=\frac{1}{\omega}$. Similarly for $k=1$,

$$
E_{3} \sim M \frac{t_{0} t_{1}^{2}}{\left(t_{1}-t_{0}\right)}
$$

and a similar minimization leads to,

$$
\begin{equation*}
\lambda_{0}^{2}=\frac{1}{2}\left[1+\frac{1}{\sqrt{2}}\right]=.85 \tag{2.15}
\end{equation*}
$$

In all these cases $E_{j}=O\left(b^{-(k+1) / 2}\right)$.

Here are two examples of $\left\{F_{n}\right\}$ for which we will check our approach and which belong to $D_{1}$ and $D_{3}$ respectively.

## 1. The Gamma Family:

Let $F_{n}$ be the distribution of $\left(S_{n}-n\right)(2 n)^{-1 / 2}$ where $S_{n}$ has the $\chi_{n}^{2}$ distribution. Evidently, we can define $G_{t}$ for $t>0$ by

$$
\begin{equation*}
G_{t}(x)=\Gamma^{-1}\left(v^{-1}\right) \lambda^{\nu} \int_{0}^{x_{t}} e^{-\lambda s} s^{\nu-1} d s \tag{2.16}
\end{equation*}
$$

where

$$
x_{t}=x v^{1 / 2}+\frac{v}{\lambda}
$$

$v=2 t^{-2}, \lambda=\frac{1}{2}$. It is not hard using standard Stirling type expansions for $\Gamma$ and its derivatives to show by writing

$$
G_{t}(x)=\frac{e^{-v} v^{v-1 / 2}}{\Gamma(v)} \int_{-\sqrt{v}}^{x}\left[e^{-u v^{-1 / 2}}\left(1+u v^{-1 / 2}\right)\right]^{\nu}\left(1+u v^{-1 / 2}\right)^{-1} d u
$$

that $A_{0}=\Phi$, the standard normal distribution and that $G_{t}$ has bounded derivatives of all orders in $t$. So $\Delta \in \mathrm{D}_{1}$ here for all $k$. Evidently, taking $\lambda=\frac{1}{2}$ plays no role and this observation applies to the standardized gamma family in general.

## 2. The binomial distribution with continuity correction

Let $F_{n}$ be the distribution of $\left(S_{n}-n_{p}\right) / \sqrt{n p q}$ convoluted with the uniform distribution on $\left(-\frac{1}{2 \sqrt{n p q}}, \frac{1}{2 \sqrt{n p q}}\right)$ where $S_{n}$ has a binomial $(n, p)$ distribution, $q=1-p$, $0<p<1$. It is well known that, see for example Feller (1971) p.540, $F_{n}$ is of the form,

$$
F_{n}(x)=\Phi(x)+n^{-1 / 2} A_{1}(x)+O\left(n^{-1}\right)
$$

However, if we analyze the remainder term further, by Theorem 23.1 p. 238 of Bhattacharya and Ranga Rao it is of the form,

$$
\begin{align*}
& F_{n}(x)-\Phi(x)-n^{-1 / 2} A_{1}(x)=n^{-1}\left(\int_{\frac{1}{2}}^{\frac{1}{2}} u S_{1}(n p+x \sigma \sqrt{n}-u) d u\right) \text {. }  \tag{2.15}\\
& \cdot P(x, \sigma)+o\left(n^{-1}\right)
\end{align*}
$$

where $\sigma=\sqrt{p q}$

$$
\begin{aligned}
& S_{1}(t)=t-\frac{1}{2}, 0<t<1 \\
& S_{1}(t+1)=S_{1}(t)
\end{aligned}
$$

Check that

$$
\begin{equation*}
\int_{-\frac{1}{2}}^{\frac{1}{2}} u S_{1}(v-u) d u=-\frac{S_{1}^{2}}{2}\left(x+\frac{1}{2}\right) \tag{2.16}
\end{equation*}
$$

We claim that unless $x=0$ and $p$ is rational the sequence $\left\{S_{1}\left(n p+\sqrt{n} \sigma x+\frac{1}{2}\right)\right.$ is uniformly distributed modulo 1 , i.e. $\#\left\{h: S_{1}\left(n p+\sqrt{n} \sigma x+\frac{1}{2}\right) \leq t, n \leq N\right\} / N \rightarrow t+\frac{1}{2}$ as $N \rightarrow \infty,-\frac{1}{2}<t<\frac{1}{2}$. A proof is sketched in the appendix.

Hence as $n \rightarrow \infty$ the coefficient of $n^{-1}$ in (2.15) ranges over an interval $\left[0, \frac{1}{8}\right]$ or $\left[-\frac{1}{8}, 0\right]$ and comes arbitrarily close to all values in the interval. So $\left\{F_{n}\right\}$ belongs to $\mathrm{D}_{3}$ for $k=1$.

Notes: 1). In a wide class of examples including the two we have discussed $A_{0}$ is known. Then if (2.1) holds for $k=r+1$ we can improve our estimate using only $k$ sample sizes and still have an error which is $O\left(b^{-(r+1) / 2}\right)$. We define $Q_{t}=\frac{G_{t}-A_{0}}{t}$ and use the estimate

$$
G_{t}^{*}=A_{0}+t \hat{Q}_{t}
$$

where $\hat{Q}_{t}$ is defined by (2.2) with $k=r$. In particular for $r=1$, the allocations (2.9),
(2.14), (2.15) give errors which are $O\left(b^{-3 / 2}\right)$. We study this approximation also by simulation in the next section.
2). In some cases, for example $F_{n}$ the $t$ distribution with $n$ degrees of freedom, the series for $F_{n}$ is in powers of $n^{-1}$. It is easy in this case also to obtain the optimal choice of $\frac{t_{0}}{t_{1}}$ for $\mathrm{D}_{2}, \mathrm{D}_{3}$ that is, for (2.4) replaced by,

$$
t_{0}^{-1}+t_{1}^{-1}=b
$$

We find for $\mathbf{D}_{2}$

$$
\begin{align*}
& n_{j}=\rho_{j} b, \quad \rho_{1}=1-\rho_{0} \\
& \rho_{0}=.5(1+\sqrt{3})=.79 \tag{2.17}
\end{align*}
$$

and for $D_{3}$

$$
\begin{equation*}
\rho_{0}=.75 \tag{2.18}
\end{equation*}
$$

If as would usually be the case in applications the $A_{j}, t$ are unknown it would seem safer to use the approximation for $t=n^{-1 / 2}$.
3). An undesirable feature of our approach is that no a posteriori estimate of the error actually incurred is available. If $t_{1}$ is small and $\Delta \in \mathrm{D}_{1}$ we can get an estimate by increasing our budget. We add $\tilde{t}^{-2} \neq t_{j}^{-2}, j=0,1$ units and calculate $G_{i}$. Now, by

$$
\begin{equation*}
G_{u}-\hat{G}_{u}=\frac{1}{2} \frac{d^{2} \Delta}{d t^{2}}(\xi)\left(t_{1}-t_{0}\right)^{-1}\left(u-t_{0}\right)\left(u-t_{1}\right) \tag{2.19}
\end{equation*}
$$

where $t<\xi<t_{1}$, for any $t \leq u \leq t_{1}$. If $t_{1}$ is small we expect the coefficient $\frac{d^{2} \Delta}{d t^{2}}$ in (2.19) to be stable, so that we obtain

$$
\begin{equation*}
\left|G_{t}-\hat{G}_{t}\right| \propto\left|\left(t-t_{0}\right)\left(t-t_{1}\right)\left(s-t_{0}\right)^{-1}\left(s-t_{1}\right)^{-1}\right|\left|G_{t}-\hat{G}_{t}\right| . \tag{2.20}
\end{equation*}
$$

If $\Delta \epsilon D_{2}$ or $D_{3}$ no realistic estimate of the error presents itself. However, suppose
as may be shown to be true in example 2 that, if $0<\lambda_{1}<\cdots<\lambda_{k}<1, a_{1}, \cdots, a_{k}$ are real, $n \rightarrow \infty, s_{j}=\left[\lambda_{j} n\right]^{-1 / 2}$,

$$
\begin{equation*}
\#\left(\Delta_{s_{j}} \leq s_{j}^{2} a_{j}: 1 \leq j \leq k\right) / n \rightarrow \prod_{j=1}^{k} G\left(a_{j}\right) . \tag{2.21}
\end{equation*}
$$

That is $s_{1}^{-2} \Delta_{s_{1}}, \cdots, s_{k}^{-2} \Delta_{s_{k}}$ are asymptotically independently distributed with common distribution $G$. This is, of course, a poor approximation if $\lambda_{j}, \lambda_{j+1}$ are too close and we are prevented from using (2.21) for the purposes of design. However if we increase our budget so as to permit calculation of $G$ at $t_{0}, t_{1}, \cdots, t_{l} k \geq 2$ and assume (2.1) it is natural to consider the estimate $\hat{G}_{t}^{l}$

$$
\begin{equation*}
\hat{G}_{t}^{l}=\hat{A}_{0}^{l}+t \hat{A}_{1}^{l} \tag{2.22}
\end{equation*}
$$

where $\hat{A}_{0}^{l}, \hat{A}_{1}^{l}$ are the weighted fixed least squares estimates of $A_{0}, A_{1}$,

$$
\begin{align*}
& \hat{A}_{1}^{l}=\sum_{i=0}^{l}\left(t_{i}-\hat{t}\right) G_{t_{i}} \sigma_{i}^{-2} / \sum_{i=0}^{l}\left(t_{i}-\hat{t}\right)^{2} \sigma_{i}^{-2}  \tag{2.23}\\
& \hat{A}_{0}^{l}=\sum_{i=0}^{l} G_{t_{i}} \frac{\sigma_{i}^{-2}}{W}-\hat{A}_{1}^{l} \hat{t} \tag{2.24}
\end{align*}
$$

where

$$
\begin{aligned}
& \sigma_{i}=t_{i}^{2} \\
& W=\sum_{i=0}^{l} \sigma_{i}^{-2} \\
& \hat{t}=\sum_{i=0}^{l} t_{i} \sigma_{i}^{-2} / W
\end{aligned}
$$

The error, $G_{t}-\hat{G}_{t}^{l}$ can be estimated by

$$
\begin{equation*}
\left\{W^{-1}+t^{2}\left[\Sigma\left(t_{i}-\hat{t}\right)^{2} \sigma_{i}^{-2}\right]^{-1} \sum_{i=0}^{l}\left(G_{t_{i}}-\hat{A}_{0}^{l}-\hat{A}_{1}^{l} t_{i}\right)^{2} \sigma_{i}^{-2}\right\}^{1 / 2} \tag{2.25}
\end{equation*}
$$

The range of validity of the approximations (2.20) and (2.25) needs to be investigated by simulation.

## 3. COMPUTATION AND SIMULATION

In this section we study the actual performance of our approximations in the examples of section 2. We also study the performance of the approximation for student's $t$ distribution where the expansion is in powers of $\frac{1}{n}$. Finally in table 6 we provide the results of a bootstrap simulation where we illustrate the operating characteristics of confidence bounds based on a Richardson extrapolation approximation compared with those based on a full bootstrap.

## a) $\chi_{n}^{2}$ approximation

We computed the Richardson extrapolation for $\frac{\chi_{n}^{2}(\alpha)-n}{\sqrt{2 n}}, \alpha=10 \%, 90 \%, 95 \%, 99 \%$, where $\chi_{n}^{2}(\alpha)$ is the $\alpha^{t h}$ percentile of the $\chi_{n}^{2}$ distribution, and compared it the Fisher square root approximation applied to the quantiles.

$$
\frac{\chi_{n}^{2}(\alpha)-n}{\sqrt{2 n}} \propto Z(\alpha)+\frac{Z^{2}(\alpha)}{2 \sqrt{2 n}}
$$

where $Z(\alpha)$ is the standard normal $\alpha$-percentile. We used $n=50,100 b=15,20,30$ and $1-\lambda=\frac{n_{0}}{b}=.1, .2, .25, .40$ where $n_{0}<n_{1}, n_{0}+n_{1}=b$. We note,
(i) The approximation improves as $b$ and $n$ increase.
(ii) The allocation $\lambda=.6$ is best, as expected.
(iii) For $n_{0}+n_{1}=15,20$ and all $\lambda$ the Richardson extrapolation is essentially as good as Fisher's approximation for the $.9, .1$ percentiles and still gives the same two significant figures as Fisher's does for the $.95, .99$ percentiles.
(iv) For $n_{0}+n_{1}=30$ it is better in all cases save one where the results are virtually equivalent. The $\lambda=.6$ allocation seems to give nearly 3 significant figures.

Table 1. Richardson extrapolation 2.3 for $\chi_{n}^{2}$

> percentiles

| $n=50$ | 10 | 90 | 95 | 99 |

In table 2 we exhibit the Richardson extrapolation results for the $\chi_{n}^{2}$ distribution using the knowledge of the limit as $n \rightarrow \infty$, as in note 1 . That is, we use the expansion

$$
\begin{aligned}
\frac{\chi_{n}^{2}(\alpha)-n}{\sqrt{2 n}} & =Z(\alpha)+A_{1} \frac{1}{\sqrt{n}}+A_{2} \frac{1}{n}+o_{P}\left[\frac{1}{n}\right] \\
& \text { or } \sqrt{n}\left[\frac{\chi_{n}^{2}(\alpha)-n}{\sqrt{2 n}}-Z(\alpha)\right]=A_{1}+A_{2} \frac{1}{\sqrt{n}}+o_{P}\left(\frac{1}{\sqrt{n}}\right]
\end{aligned}
$$

where $Z(\alpha)$ is the $\alpha$ percentile of the standard normal. $A_{1}, A_{2}$ are estimated using $\chi_{n_{0}}^{2}$ and $\chi_{n_{1}}^{2}$. The results are extremely good for both $n=50$ and $n=100$ (which we omit). The extrapolation, even for $n_{0}+n_{1}=15$ and $\lambda=.9$ gives three significant figures for all percentiles. For $n_{0}+n_{1}=30$ it often gives five significant figures.

Table 2: Richardson extrapolation (Note 1) for $\chi_{50}^{2}$.

Student's $t$ distribution has an expansion in powers of $\frac{1}{n}$. The Richardson extrapolation (2.3) with $\frac{1}{\sqrt{n}}$ gave no improvement over the ordinary normal approximation as expected. In table 3 we present the Richardson extrapolation to the $t$ distribution as in note 2 . and compare these results to the normal approximation. We looked at the same values of $n, b, \lambda, \alpha$ for approximation to $t_{n}(\alpha)$, the $\alpha^{t h}$ percentile of the $t$ distribution with $n$ degrees of freedom. For $\lambda=.6 b=30$ the approximation is valid to 3 significant figures for $n=100$ in all but one case and improves on the normal approximation.

Tables 4,5 give the Richardson extrapolation for the continuity corrected binomial distribution. That is we define

$$
B_{n}(s)=\sum_{k=0}^{[s]}\left[\begin{array}{l}
n \\
k
\end{array}\right] p^{k}(1-p)^{n-k}+(s-[s])\left[\begin{array}{c}
n \\
{[s]+1}
\end{array}\right] p^{[s]+1}(1-p)^{n-1-[s]}
$$

and $Q_{n}(u)=B_{n}\left(n p+u \sqrt{n p(1-p))}\right.$. We approximated the percentiles $Q_{n}{ }^{-1}(\alpha)$ for $n, b, \lambda$ as before with $p=.2, .4$. Note that,
(i) The $\lambda=.75$ allocation seems to work best but differs little from $\lambda=.8, .9$. On the other hand $\lambda=.6$ is poorer. This is in agreement with our theory for class $D_{3}$. For $p=.2, n=50 ; 100 b=15 ; 20$ the $\lambda=.75$ allocation does as well as the normal. For $b=20 ; 30$ it's better, typically giving one more significant figure. For $p=.4$, it is in general poorer though far from terrible.

This is understandable since for $p=.5, A_{1}=0$ and the extrapolation is adding noise to the normal approximation.

In table 6 we show the results for the bootstrap experiment. The "population' is $\sigma^{2} \chi_{1}^{2}$ and we are interested in a confidence bound for $\sigma$. We study the unadjusted bootstrap i.e. the percentiles of the bootstrap distribution of $\sqrt{\bar{X}_{n}}$ where $\bar{X}$ is the sample mean. For $n=50,100,500$ we took 500 samples of size $n$ from $\chi_{1}^{2}$. For each sample we took 1,000 bootstrap samples and computed the .05 .1 and .95 percentiles of the bootstrap distribution of $\sqrt{\overline{X_{n}}}$ for sample size $n_{0}, n_{1}, n$. We study the behavior of the " $90 \%$ " lower confidence bound and the " $90 \%$ "' confidence interval i.e. the .1 percentile and the interval between the .95 and .05 percentiles.

For each $n$ we count the number of times the population parameter falls inside the confidence set, out of the 500 samples. We computed the average and S.D of the rescaled lower bound, i.e. of

$$
\sqrt{n}\left(1-G_{n}^{*-1}(.1)\right)
$$

and of the rescaled interval i.e.

$$
I_{n}^{*}(.9)=\sqrt{n}\left(G_{n}^{*-1}(.95)-G_{n}^{*-1}(.05)\right)
$$

where $G_{n}^{*-1}(\alpha)$ is the $\alpha$ percentile of the bootstrap distribution of $\sqrt{\bar{X}}$. Table 6 shows clearly that Richardson extrapolation is a good approximation to the full bootstrap and is not very sensitive to the allocation of $n_{0}, n_{1}$. The last entry gives estimated computing times on Sun workstations at Berkeley. The linear saving in the sample size we expected is confirmed.

## 4. APPENDIX: theory for example 2

We establish the claim asserted in example 2 in the form of a theorem.
Theorem: $\quad[a n+b \sqrt{n}]$ is uniformly distributed (u.d.) mod 1 unless $b=0$ and $a$ is rational.

Proof: We refer repeatedly to the text of Kuipers and Niederreiter (K-N). Suppose $a$ is irrational. Note that

$$
a(n+1)+b \sqrt{n+1}-a n-b \sqrt{n}=a+b 0\left(n^{-1 / 2}\right) \rightarrow a
$$

as $n \rightarrow \infty$. By theorem 3.3 of $(\mathrm{K}-\mathrm{N})$, $a n+b \sqrt{n}$ is u.d. $\bmod 1$.
If $a$ is rational we apply
Lemma: Let $b_{n}$ be a sequence such that $\left\{b_{s j+k}\right\}_{j \geq 1}$ is u.d. $\bmod 1$ for $s \neq 0,0 \leq k \leq s$. Then if $a$ is rational, $a=\frac{r}{s}, a n+b_{n}$ is u.d. $\bmod 1$.

Proof: Check Weyl's criterion (K-N). Let $n=m s$. Then

$$
\begin{align*}
& \left.\left|\frac{1}{n} \sum_{l=1}^{n} e^{2 \pi i h\left(a_{l}+b_{l}\right)}\right|=\left\lvert\, \frac{1}{m s} \sum_{j=0}^{m-1} \sum_{k=0}^{s-1} e^{2 \pi i h\left[r \frac{k}{s}+b_{s j+k}\right.}\right.\right] \mid  \tag{4.1}\\
& \leq \frac{1}{s} \sum_{k=0}^{s-1}\left|\frac{1}{m} \sum_{j=0}^{m-1} e^{2 \pi i h b_{s j+k}}\right| \rightarrow 0
\end{align*}
$$

as $m \rightarrow \infty$ by Weyl's criterion applied to $\left\{b_{s j+k}\right\}_{j \geq 1}$. If $n=m s+b, 0<b<s$, the difference from (4.1) is at most $\frac{b}{m s} \rightarrow 0$. The lemma follows by Weyl's criterion. Q.E.D.

Put $b_{n}=b \sqrt{n}$. If $b>0 b_{s(j+1)+k}-b_{s j+k}$ is decreasing to 0 in $j$ since $\sqrt{x}$ is concave. Moreover,

$$
j\left(b_{s(j+1)+k}-b_{s j+k}\right)=\Omega\left(j^{1 / 2}\right) \rightarrow \infty .
$$

By Fejer's theorem (K-N Theorem 2.5) $\left\{b_{s j+k}\right\}$ is u.d. mod 1 and the theorem follows.
